Short title: Hemidiaphragm paralysis and sleep

Key words: REM-sleep, respiratory muscles, electromyogram

ABSTRACT

Rationale Few data exist concerning sleep in patients with hemidiaphragm paralysis or weakness. Traditionally such patients are considered to sustain normal ventilation in sleep.

Patients&Methods We measured diaphragm strength to identify patients with unilateral paralysis or severe weakness. Patients underwent polysomnography with additional recordings of the transesophageal electromyogram of the diaphragm and surface electromyogram of extra-diaphragmatic respiratory muscles. We compared these data to 11 normal, healthy subjects matched for sex, age and body-mass-index.

Results We studied 11 patients (6men, mean(SD) age 56.5(10.0)years, body-mass-index 28.7(2.8)kg/m^2) with hemidiaphragm paralysis or severe weakness (unilateral twitch transdiaphragmatic pressure 3.3(1.7)cmH$_2$O). They had a respiratory disturbance index of 8.1(10.1)/h during non-rapid-eye-movement sleep, and 26.0(17.8)/h ($p<0.0001$) during rapid-eye-movement sleep (control group 0.4(0.4) and 0.7(0.9)/h; patient vs control group: p=ns, and $p<0.0001$). The diaphragm electromyogram, as a percentage of maximum, was double that of the control group in non-rapid-eye-movement sleep (15.3(5.3) vs 8.9(4.9)%max; $p<0.05$) and increased in rapid-eye-movement sleep (20.0(6.9)%max; $p<0.05$), whilst normal subjects sustained the same level of activation (6.2(3.1)%max;p=ns).

Conclusion Patients with unilateral diaphragm dysfunction are at risk of developing sleep-disordered breathing during rapid-eye-movement sleep. The diaphragm electromyogram, reflecting neural respiratory drive, is doubled in patients compared to normal subjects, and increases further in rapid-eye-movement-sleep.

INTRODUCTION

Patients with diaphragm paralysis may develop breathlessness as a consequence of the reduced capacity of the respiratory system [1, 2]. During sleep in normal subjects ventilation depends particularly on diaphragm function [3]. In patients with diaphragm dysfunction, during both rapid-eye-movement-sleep (REM-sleep) and wakefulness, electromyographic activity of the extradiaphragmatic respiratory muscles [4-7] is higher than normal as a compensation for diaphragm weakness.

The results of studies looking at breathing patterns in unilateral (UDP) or bilateral (BDP) diaphragm paralysis have been inconsistent [8-13]. Some investigators have reported disturbed sleep, inadequate ventilation during sleep, and daytime sleepiness caused by diaphragm dysfunction [8, 11] while others have found little impact on the normal sleep pattern unless there is additional load on the ventilatory system [9, 10, 14]. Previous studies either did not focus on UDP (had mixed populations of BDP and UDP [8, 9] or exclusively BDP [5, 11]), did not distinguish between REM and NREM-sleep associated SDB [10], did not characterize the subjects other than with non-invasive measurements [15] or studied animal models. The studies that did not perform invasive respiratory muscle tests therefore have not tested a homogenous population of UDP patients and it is likely that the different results reflect the heterogeneity of the patients studied, in terms of weakness and ventilatory load.

Clinically it is often assumed that patients with UDP have no problems during sleep unless other comorbidities are present [9, 10]. We have previously noted that some patients with clinically diagnosed UDP present with daytime symptoms, including breathlessness and sleepiness [14]. In these patients sleep-disordered breathing (SDB) and, in particular during phases of REM-sleep, hypoventilation could occur [8].

Hypothesis

We hypothesized that patients with unilateral diaphragm paralysis or severe weakness and no other respiratory abnormalities can develop SDB during REM-sleep, we therefore investigated a group of UDP patients during sleep. To our knowledge, this is the first study looking at REM-sleep related SDB in an accurately diagnosed population with UDP.

METHODS, MATERIALS AND PATIENTS

Study Subjects

39 patients referred with a clinical diagnosis of hemidiaphragm paralysis had comprehensive respiratory muscle function assessment. These tests demonstrated that 14 of them had BDP, 17 had UDP or severe weakness, 8 had normal diaphragm function. Eleven of the patients with UDP or severe weakness consented to polysomnography. All of them had a unilateral twitch transdiaphragmatic pressure (Pdi) of $<6cmH_2O$ with normal twitch pressures on the contralateral side.

Eleven normal subjects served as a control group. All participants gave written consent, the study was approved by King´s College Hospital Research Ethics Committee.

Methods

The following assessments were made *(additional detail on the methods for making these measurements is provided in an online supplement)*:

1.) **Questionnaires:**

a) Medical Research Council (MRC) dyspnoea scale.

b) The Chronic Respiratory Diseases Questionnaire (CRDQ) and St George's Respiratory Questionnaire (SGRQ).

c) The Epworth Sleepiness Scale (ESS).

d) History of changes in sleep, problems with posture and breathlessness were noted.

2.) Lung function tests and arterialised earlobe blood gases:

a) The patients underwent spirometry according to the British Thoracic Society (BTS) guidelines [16]. Vital capacity was measured in the sitting and supine position.

b) Arterialised earlobe blood was collected into a capillary tube and analysed (Bayer Rapidlab 248®, Diamond Diagnostics®, MA/USA).

3.) Respiratory muscle tests:

We measured inspiratory, diaphragm specific, and expiratory muscle strength according to the ATS/ERS statement on respiratory muscle testing [17].

Electromyogram of the Diaphragm (EMGdi)

A multipair electrode catheter (Yinghui Medical Tech Ltd®, Guangzhou, China) was inserted via one nostril to record the transoesophageal EMGdi, as previously described [18, 19], connected to RA-8® amplifiers (Yinghui Medical Tech Ltd®, Guangzhou, China) that further transmitted the signal to an analog-to-digital converter, Powerlab® 16/30 (ADInstruments®, Colorado Springs/CO, USA), running Chart® 5.4 (ADInstruments®, Colorado Springs/CO, USA).

Compound muscle action potential (CMAP) amplitude and latency after magnetic stimulation of the phrenic nerves were measured. Reference values for the right phrenic nerve values are CMAP 1.45 (0.35) mV, latency 6.9 (0.9) ms and for the left phrenic nerve CMAP 1.68 (0.47) mV and latency 7.6 (0.7) ms [20].

Electromyogram of extra-diaphragmatic respiratory muscles

The EMG of the neck muscles, parasternal intercostals, and abdominal muscles was recorded using surface electrodes (Kendall Arbo®, Tyco Healthcare®, Neustadt, Germany) from standard positions [21-24].

The EMG was recorded during the following manoeuvres that have been described to achieve maximum activation of the diaphragm [25, 26]; at least 5 attempts were performed for each, until consistent results were achieved.

− whilst breathing in as much as possible (total lung capacity manoeuvre)

− whilst breathing in as hard as possible against a closed airway (PImax manoeuvre)

− maximal sniffs

− maximum voluntary ventilation over 15s ("sprint MVV")

− Additionally, during maximal coughs and expiration against an occluded valve (PEmax manoeuvre).

4.) Overnight surveillance

Full polysomnography was performed using Alice 4® equipment (Respironics®, Murrysville/PA, USA). Sleep and respiratory events were scored with standard terminology [27].

Analysis

The overnight EMG data were normalised to maximum EMG activity during a maximal effort and expressed as a percentage of maximum (%max) EMG activity. The researcher analysing the EMG data was blinded to the results of the polysomnography analysis. We analysed 10min of a deep sleep cycle and compared this to 10min of a REM sleep cycle. To select

these periods we chose the first occurrence of such periods over the night. If a single sleep stage did not last 10 minutes, the remaining time was analysed from the next sleep cycle. There was a significant impact of posture and arousal on the EMG_{di} signal. Therefore, we only compared REM to NREM data that were obtained in the supine position and excluded arousal events. We only included sleep stage 2 and 3 in the analysis, because of the unstable nature of sleep stage 1. Results were further analysed using SPSS[®]13 (SPSS[®], Chicago/IL, USA) and following testing for normalities expressed as mean (SD). A p-value <0.05 was considered significant. The independent variables t-test was used for group comparisons. In addition, we used a repeated measure one-way ANOVA for the analysis of REM and NREM-sleep parameters within and between the groups, with post-hoc analysis using Bonferroni´s correction for multiple comparisons. A multiple linear regression analysis to find independent predictors of REM-related SDB was not possible due to the low sample size (n=22), therefore, we report the r-values for the best fit between potential predictors (sex, age, BMI and diaphragm weakness) and REM-related SDB [28].

RESULTS

The characteristics of the patients are given in Table 1. Nine of eleven patients preferred to sleep with the normal hemidiaphragm downwards, two had no preference, and none preferred sleeping with the abnormal hemidiaphragm downwards (normal subjects: n=11 without preferred sleeping side; p=0.035). Thoracoabdominal paradox was observed in eight patients (no 1-5,9-11) and was associated with a weaker hemidiaphragm (unilateral Twitch Pdi 2.6 (1.3) vs 4.9 (1.5) cmH_2O; p=0.029). Although there was a trend for patients to be older and have a slightly higher BMI, the patient group was not significantly different from the control group in terms of age (56.5(10.0) vs 44.5(21.4) years; p=0.106), sex (both groups 6m : 5f; p=1.0), and BMI (28.7(2.8) vs 26.3(2.6) kg/m^2; p=0.051) (Table 1).

All but one patient (Patient 8) performed the volitional respiratory muscle tests satisfactorily. Twitch Pdi and Sniff Pdi were reduced in the patients. PImax, Sniff Poes and Sniff Pnasal were also reduced, whereas PEmax, cough Pgas and Twitch T10 were normal (Table 2, *additional detail on the individual results is provided in an online data supplement*).

Phrenic nerve latency was prolonged in nine out of eleven patients on the weak side, and prolonged in five out of eleven patients on the strong side. The compound muscle action potentials (CMAP) were markedly reduced on the weaker side, with ten out of eleven patients having a CMAP less than the lower limit of normal [20]. On the strong side the CMAP was markedly reduced in four patients (Table 3).

The FEV_1 was low in the patient group and compared to the normal group the FEV_1/VC ratio indicated a mild obstructive defect. Vital capacity was reduced in the patient group and showed a further fall when supine; patient no 8 was excluded from the analysis of these data because of inability to perform the VC manoeuvre lying supine. Although none of the patients was hypercapnic, PaO_2 was mildly reduced (Table 4).

During polysomnography we observed frequent hypopnoeas and apnoeas in REM-sleep (Figure 1). Only two patients (n° 7 and 8) had no SDB, and they had the highest Twitch Pdi on their weak side (5-6cmH$_2$O). Baseline oxygenation in the group was normal during NREM-sleep, but dropped during hypopnoeas in REM-sleep. The RDI in NREM-sleep was more variable in the UDP patients, but not significantly higher than in the normal subjects (Table 5). The RDI was, in NREM-sleep, elevated in a subgroup of patients who had a thoracoabdominal paradox (p=0.002).

Quality of life was significantly reduced in patients compared to the control group (*additional results on quality of life are provided in an online data supplement*). All domains of the SGRQ and the CRDQ were statistically different in the patient group compared to control subjects, reaching more than the minimal clinical important difference. The largest differences were observed in the CRDQ "dyspnoea" domain and SGRQ "activity" and "symptoms" scores. The MRC dyspnoea scale (2.4 (1.0) vs 1.2 (0.4) points, $p=0.002$) and the Epworth sleepiness scale (11.9 (5.7) vs 3.7 (2.8) points, $p<0.001$) were significantly increased in patients (Table 1).

The electromyogram of the diaphragm (%max EMGdi) was elevated in patients with UDP in sleep (15.3 (5.3) vs 8.9 (4.9) %maxEMGdi in NREM; $p<0.05$; Figure 2a and 3). While levels of EMGdi were sustained during NREM and REM-sleep phases in the control group (8.9 (4.9) and 6.2 (3.1) %maxEMGdi; p=ns) they were increased in the patients during REM-sleep (from 15.3 (5.3) to 20.0 (6.8) %maxEMGdi; $p<0.05$; Figure 2a and 3). There was no difference in the activation of the neck muscles between patients and control subjects in NREM sleep (p=ns; Figure 2b). In REM-sleep activation of the neck muscles decreased only in the normal subjects ($p=0.032$, Figure 2b).

The parasternal intercostals were equally activated in NREM and REM sleep in patients and control subjects (p=ns). There was no significant difference between patients and normal subjects in the activation of the abdominal muscles (p=ns), although additional activation was observed in some patients during REM-sleep.

The variability of EMGdi during sleep, as measured by the standard deviation of the mean of the EMGdi (as percent of maximum) of every breath for a 10-minute period, in patients with UDP was higher than in normal subjects in both REM- and NREM-sleep ($p<0.01$). It was 6.9%maxEMGdi in REM and 5.4%maxEMGdi in NREM sleep in UDP patients, whilst it was

2.1%maxEMGdi in REM and 2.4%maxEMGdi in NREM sleep in healthy subjects. Only one patient with UDP, who had no SDB, had a standard deviation < 4%maxEMGdi (patient no 7=2.9%), whilst the only normal subject who reached a SD >3%maxEMGdi was a snorer. The variability of the EMG signal of the neck muscles over a 10-minute period, measured as described above, was similar in both groups in NREM-sleep (3.2 vs 4.0%maxEMGneck; p=ns) and lower in the normal subjects in REM-sleep (2.6 vs 4.4%maxEMGneck; p<0.05).

The only variable significantly correlated to REM-RDI (1/h) was diaphragm weakness (r=0.784, p<0.001). Age (r=0.332, p=0.132), sex (r=-0.118, p=0.60), and BMI (r=0.381, p=0.08) were not significantly correlated to REM-sleep related SDB.

DISCUSSION

In patients with hemidiaphragm paralysis or severe weakness who present with related respiratory symptoms neural respiratory drive to the diaphragm in NREM-sleep is significantly increased compared to that of healthy individuals. While there is a decrease in the activation of peripheral skeletal muscle in the healthy population during REM-sleep [29], and levels of neural respiratory drive remain the same, the response of UDP patients is different. They activate the diaphragm more during REM-sleep. In addition, like BDP patients [5], they also activate their accessory respiratory muscles (neck muscles) during REM-sleep to attenuate hypoventilation, although the use of these muscles for posture, as well as movement artefacts, probably contributed to the wide spread of the data. During inspiration, in REM-sleep, the abdominal muscles are active in some patients. Whilst this is likely to be a compensatory response, its function is not completely understood and requires further exploration.

We found a significant increase in respiratory-related events during REM-sleep, causing SDB – this is consistent with the finding in patients with BDP having only REM-sleep related SDB

[11, 30]. Most of the events were hypopnoeas, although there was some obstruction in two patients that became worse during REM-sleep. All patients with a Twitch Pdi of less than 5cmH$_2$O on the weaker side had REM-related SDB. Two patients with a Twitch Pdi over 5cmH$_2$O had no SDB, suggesting a threshold level of diaphragm dysfunction below which SDB is more likely.

The predominant mechanism of respiratory events during REM-sleep in this patient population was of central origin, according to the criteria of the American Academy of Sleep Medicine Task Force (point 4.2.2.1 – definition central apnea/hypopnea events) [31].

In contrast neural respiratory drive, whilst relatively low during the onset of an obstructive apnoea or hypopnoea, rises parallel to inspiratory pressures during the time of upper airway occlusion, reflecting the respiratory effort against a high resistance [32]. In the UDP patients there is a different pattern: mean drive is relatively high during REM-sleep falling only slightly during phasic REM, and flow indicates that the upper airway is open, and there is no snoring. In three UDP patients in whom we measured transdiaphragmatic pressure overnight we could show that the respiratory events during REM-sleep were not associated with increased inspiratory pressures.

We conclude that in the population studied the main mechanism leading to REM-related SDB was central hypopnoea that occurred despite an elevated overall mean neural drive, because the respiratory muscle pump is not able to sustain sufficient alveolar ventilation (Figure 4).

The observed changes in sleep pattern and habits indicate compensatory mechanisms are active even in patients without overt SDB. In some of the patients with UDP thoracoabdominal paradox was observed and these patients had weaker diaphragms and more severe SDB. In addition, the self reported changes of sleeping side preference make it likely that subjects have a more improved respiratory function when lying with the stronger

hemidiaphragm dependent. Changes in sleep habits or postures should be inquired for when UDP is suspected.

The level of neural drive, in terms of EMGdi%max, is a measure of the load:capacity balance of the ventilatory system. Measuring neural respiratory drive in terms of transoesophageal EMGdi may offer a way of detecting SDB, assessing the response to therapy, and may be a sensitive tool to record changes occurring in response to increased resistance in the pharynx as in obstructive sleep apnoea [32]. The measurement of the EMG of the neck muscles, in REM-sleep, may also be useful. We have shown that healthy subjects, provided they do not snore, have little variation in EMGdi%max. Variability of the signal, normalised to maximum manoeuvres, may thus be a marker for how disturbed sleep is. The same is true for the EMGneck%max during REM-sleep.

The quality of life measures show that patients with UDP or severe weakness are more symptomatic than normal subjects. UDP can cause breathlessness and sleepiness, as indicated by changes in the CRDQ sypnoea score, the MRC dyspnoea scale and the Epworth sleepiness scale. It is of note that thoracoabdominal paradox only occurred in patients with a unilateral Twitch Pdi of less than 5cmH$_2$O and all such patients had SDB. This physical sign may serve to identify patients at risk of SDB.

Whereas bilateral diaphragm paralysis is considered a potential health risk [13], unilateral paralysis of the diaphragm is usually considered to be benign. Our data show that UDP can lead to sleep-disordered breathing and reduced quality of life. The weaker the hemidiaphragm the more likely is sleep-disordered breathing to develop.

It is important to consider factors that could increase the risk of SDB in UDP. Obesity would be expected to be important. It imposes an additional load on the reduced capacity of the respiratory system, thereby predisposing to hypoventilation [6]. However, over the range of BMI of the patient population studied diaphragm weakness, as measured by unilateral Twitch Pdi, was the only factor correlated with REM-related sleep-disordered breathing.

Hart et al [7] showed an unexpectedly large reduction in exercise capacity in patients with UDP. Laroche et al [33] found UDP patients to be more breathless than expected. An early study by Douglas and Clagett [34] found 10-24% of patients with hemidiaphragm paralysis to be breathless. Patakas et al [15] described twelve patients with nocturnal hypoxia and presumed unilateral diaphragmatic paralysis, but characterised the patients insufficiently to diagnose unilateral phrenic nerve dysfunction accurately. As we have shown in this study, only 17 out of 39 patients who were clinically suspected to have UDP actually had unilateral involvement when assessed with electrophysiological tests of the phrenic nerves. Nevertheless, the findings from previous studies lend support to the hypothesis that patients with UDP may be importantly symptomatic.

Limitations to this study

The clinical diagnosis of hemidiaphragm paralysis or weakness is not accurate and definitive assessment requires measurement of transdiaphragmatic pressures [35]. Clinically, patients suspected as having hemidiaphragm paralysis can have either bilateral involvement or no weakness at all, despite the chest X-ray showing an elevated hemidiaphragm [35]. This causes problems when recruiting patients to clinical studies. Patients with severe symptoms and weakness are more likely to be referred, and subsequently participate in clinical studies. Thus, the results of the present study may not be generalizable to all patients with hemidiaphragm

paralysis. However, our data clearly show that UDP can be symptomatic and reduce quality of life.

This study did not measure $PaCO_2$ overnight and therefore cannot define the degree of REM-sleep related hypoventilation. However, the observed pathophysiology seems to be similar to that of patients with BDP in whom CO_2-retention has been measured and REM-sleep hypoventilation confirmed [12,13]. It is therefore likely that the REM-related frequent hypopnoeas and apnoeas in UDP patients cause hypoventilation.

We acknowledge that the RDI for the total sleep time is relatively low in the UDP patients. This is because the sleep-disturbance is largely confined to the REM-sleep period with only mild or no sleep-disordered breathing in NREM-sleep. However, the relatively severe disturbance during REM-sleep causes clinically relevant symptoms, as shown by the reported symptom scores and the quality of life data. These patients show compensatory patterns of respiratory muscle recruitment, indicating a response of the nervous system to compensate for weakness, particularly during REM-sleep. Similar to the total sleep time RDI, the periods of oxygen desaturation are also relatively short in these patients.

A potential limitation in the study is that the patient group tended to be more obese than controls. However, in the patients studied, REM-related SDB was independent of BMI.

In this study arousals occurred more often than in a normal healthy population in both patients and control subjects. This is likely to be due to the complexity and invasiveness of the study (polysomnography, transoesophageal catheter, surface EMGs). However, the arousals in the normal subjects were not caused by respiratory effort (RERAs). These minor disturbancies of

sleep patterns were the same in patients and the control group. The REM-related hypopnoeas in the patient group cannot therefore be attributed to the study setup.

The surface EMG provides a relatively nonspecific way to measure the activity of a particular muscle. We are aware that the positioning of the electrodes on the surface of the sternocleidomastoid and the rectus abdominis may have recorded EMG signals of other neck or abdominal muscles (hence the labelling of traces as EMG_{neck} or $EMG_{abdomen}$). In addition, we acknowledge that the maximisation manoeuvres for expiratory abdominal muscle activation have not been standardized in previous studies. However, two standard manoeuvres (PEmax and Cough Pgas) showed good reproducibility of EMG data and expiratory muscle strength was similar between the two groups.

It might be of concern that the inspiratory activation of the abdominal muscles observed in some patients could have been diaphragm activity detected by the surface EMG electrodes. No inspiratory surface EMG activity was detected in REM-sleep in normal subjects. Our own in-house data from patients with BDP, and therefore no spontaneous diaphragm EMG activity, show the same inspiratory activity of the abdominal muscles during sleep. We are therefore confident that we measured activation of the abdominal muscles, without contamination from the diaphragm. The abdominal EMG activity referred to was observed during inspiration. It is not completely understood how inspiratory acitivity of otherwise expiratory muscles can help to compensate for diaphragmatic muscle weakness. However, we wanted to clarify that this inspiratory activity was also observed in BDP patients in whom no spontaneous diaphragmatic EMG could be recorded. The observed surface EMG signals in such patients have to originate in the abdominal muscles. Abdominal muscle activation in patients with a thoracoabdominal paradox might result in a stabilization of the anterior abdominal wall, avoiding inspiratory inward movement of the abdomen. This would also help

to stabilize the weaker hemidiaphragm which otherwise would be pulled upwards by the intrathoracic negative pressure.

Conclusion

Patients with hemidiaphragm paralysis or severe weakness can develop REM-related SDB, independent of body-mass, sex and age. In such patients, frequent hypopnoeas during REM-sleep with compensatory activation of the accessory respiratory muscles is observed. There seems to be a threshold of unilateral Twitch Pdi ($5cmH_2O$) above which patients with unilateral diaphragm weakness do not develop SDB. It is sensible to screen for and address long-term risks of SDB in symptomatic patients with UDP. Once the diagnosis is confirmed treatment, including non-invasive ventilation, should then be considered to improve health status.

<center>**Table Legends**</center>

Table 1: Clinical features of patients. Age in years, BMI=Body-Mass-Index in kg/m^2, MRC = Medical Research Council dyspnoea scale, ESS = Epworth Sleepiness Scale, UDP = unilateral diaphragm paralysis or severe weakness, Paradox = thoraco-abdominal paradox by inspection and analysis of traces of oesophageal and gastric pressure swings, Sleeping Side = preferred sleeping position.

Table 2: Results of respiratory muscle function tests for control group and patients. All pressures recorded in cm H$_2$O. Tw Pdi = twitch transdiaphragmatic pressure, Sniff Pdi = sniff transdiaphragmatic pressure, Sniff Poes = sniff oesophageal pressure, Sniff Pnasal = sniff nasal pressure, PImax = maximal inspiratory mouth pressure, PEmax = maximal expiratory mouth pressure, cough Pgas = cough gastric pressure, Tw T10 = gastric pressure following magnetic stimulation at level of T10. Tw T10 was not obtained in four patients (N/A). All twitches were elicited with magnetic stimulation. The significance of the differences between patient and control group are given by the p-values.

[a] unilateral Twitch Pdi in normal subjects with normal hemidiaphragm strength measured on the less strong side.

[b] unilateral Twitch Pdi in normal subjects with normal hemidiaphragm strength measured on the stronger side.

Table 3: Phrenic nerve conduction studies. Latencies in ms, CMAP=compound muscle action potential in mV. The significance of the differences between patient and control group are given by the p-values. Weaker sides of the hemidiaphragm are indicated, with a ratio (R:L).

[a] Phrenic nerve latencies and CMAPs in normal subjects with normal hemidiaphragm strength measured on the less strong side.

Phrenic nerve latencies and CMAPs in normal subjects with normal hemidiaphragm strength measured on the stronger side.

Table 4: Pulmonary function test results. FEV_1 as percent predicted, vital capacity (VC) as percent predicted, FEV1/VC ratio as a percentage, VCdrop=fall in VC when changing from the sitting to the supine position as a percentage (patient no 8 was excluded due inability to perform the manoeuvre), PaO_2 and $PaCO_2$=partial pressures of oxygen and carbon dioxide in kPa. Differences between patients and control group are indicated by the p-values.

Table 5: Results of polysomnography. TST=total sleep time in minutes, REM=rapid-eye-movement sleep in minutes, RDI=respiratory disturbance index in events/h, SaO_2=oxygen saturation (%). Differences between patients and control group are indicated by the p-value.

Table 1

Pt	Sex	Age	BMI	UDP	MRC	ESS	Paradox	Sleeping side	Comorbidities
1	M	53	26.8	Right	1	18	Yes	Left	None
2	F	64	28.8	Right	2	10	Yes	None	Ulcerative colitis
3	M	58	28.7	Right	2	16	Yes	Left	None
4	M	76	28.4	Right	4	13	Yes	Left	Gastrooesophageal reflux, chronic anaemia
5	M	59	29.6	Right	2	6	Yes	Left	Coronary artery disease
6	F	62	29.6	Right	2	3	No	Left	None
7	F	47	32.5	Right	3	14	No	Left	Depression
8	F	44	22.9	Right	4	17	No	None	Depression
9	F	57	30.9	Left	4	21	Yes	Right	Diabetes mellitus
10	M	41	31.8	Right	2	9	Yes	Left	None
11	M	61	25.8	Right	3	7	Yes	Left	None

Table 2

	UDP Group	Control Group	p-value
Tw Pdi, bilateral	17.3 (5.0)	26.2 (5.5)	0.001
Tw Pdi, weak side	3.3 (1.7)	10.4 (1.9)[a]	<0.001
Tw Pdi, strong side	11.2 (2.2)	13.4 (3.3)[b]	0.083
Sniff Pdi	71.0 (40.2)	136.7 (39.9)	0.001
Sniff Poes	63.6 (34.5)	112.7 (39.5)	0.006
Sniff Pnasal	56.2 (31.3)	99.6 (43.6)	0.014
PImax	49.4 (29.8)	110.0 (43.7)	0.001
PEmax	96.8 (33.7)	118.4 (50.9)	0.253
Cough Pgas	186.1 (50.8)	202.7 (63.2)	0.504
Tw T10	43.7 (33.5)	35.3 (11.0)	0.444

Table 3

	UDP Group	**Control Group**	**p-value**
Latency on weak side (ms)	11.3 (3.0)	6.7 (0.8)[a]	<0.001
CMAP on weak side (mV)	0.370 (0.254)	1.405 (0.430)[a]	<0.001
Latency on strong side (ms)	9.3 (2.2)	6.9 (1.0)[b]	0.004
CMAP on strong side (mV)	0.891 (0.299)	1.359 (0.370)[b]	0.004
Ratio weak:strong side	10:1 (r:l)		

Table 4

	UDP Group	**Control Group**	**p-value**
FEV1	62.5 (16.6)	99.0 (13.1)	<0.001
VC	74.4 (18.4)	102.3 (22.8)	0.005
FEV1/VC ratio	71.3 (10.5)	80.8 (5.2)	0.014
VC drop	20.7 (5.7)	6.4 (4.7)	<0.001
PaO$_2$	10.08 (1.19)	12.10 (1.42)	0.002
PaCO$_2$	4.92 (0.33)	5.07 (0.45)	0.389

Table 5

	UDP Group	**Control Group**	**p-value**
TST	260.4 (108.2)	298.5 (77.7)	0.353
REM-time	36.5 (21.0)	53.7 (22.3)	0.078
RDI, $_{REM}$	26.0 (17.8)	0.7 (0.9)	<0.001
RDI, $_{NREM}$	8.1 (10.1)	0.4 (0.4)	0.080
SaO$_2$, $_{REM\ average}$	92.9 (2.3)	95.9 (1.6)	0.002
SaO$_2$, $_{NREM\ average}$	93.6 (1.9)	95.5 (1.6)	0.024
SaO$_2$, $_{Nadir}$	85.9 (4.6)	92.0 (2.1)	0.001

Figure 1: Mean (SEM) of the respiratory disturbance index (RDI) for patients (circles) and control group (squares). There is a significant increase of the RDI in REM sleep in patients with UDP ($p < 0.0001$). The group-difference is significant for REM-sleep ($p < 0.0001$). ns=not significant.

Figure 1

Figure 2a: Electromyogram of the diaphragm. Box-Whisker Plot showing the median (thick black bar), quartiles, and extreme values. The box represents the interquartile range which contains 50% of the values, the whiskers extend from the box to the highest and lowest value. Neural respiratory drive of patients (left) as measured by the EMGdi (%max) during NREM-

sleep (dark shading) is double that of the normal subjects (right). It increases with REM-sleep (light shading), whilst normal subjects have a fall in their EMGdi (%max). * p<0.05, *** p<0.0001, ns=not significant.

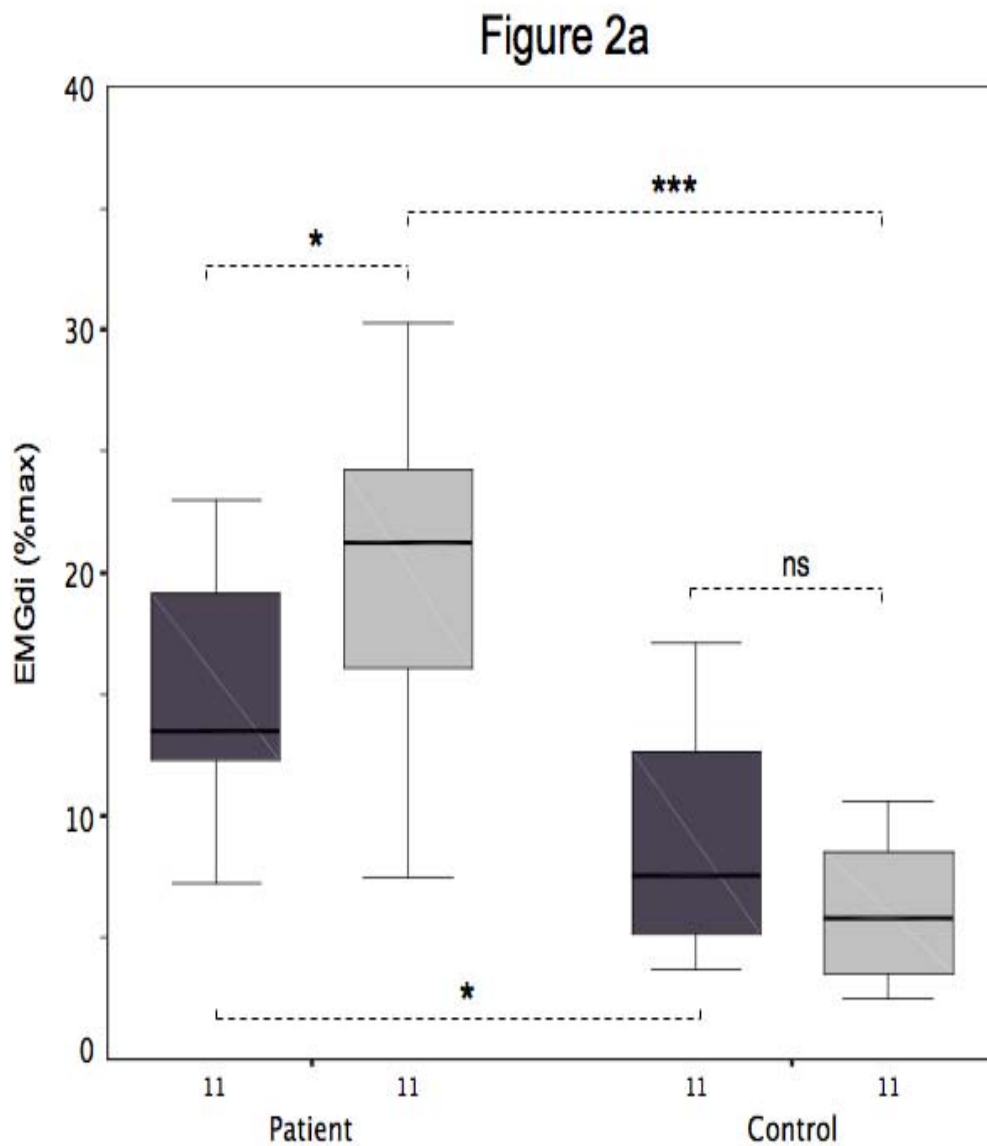

Figure 2b: Electromyogram of the neck muscles. Box-Whisker Plot showing the median (thick black bar), quartiles, and extreme values. The neck muscles in patients (left) remained active in REM-sleep (light shading). * p<0.05, ns=not significant.
Figure 3: 15s sample of an EMG signal of the diaphragm (EMGdi, μV) and the root-mean-square (RMS, 50ms time constant, moving average, μV) during NREM (left) and REM (right) sleep in a patient with UDP (top) and in a normal subject (bottom). Inspiratory activity of the diaphragm is marked with arrows. Note the increase of neural respiratory drive in the patient during REM-sleep, whilst the normal subject exhibits a lower level of activation.
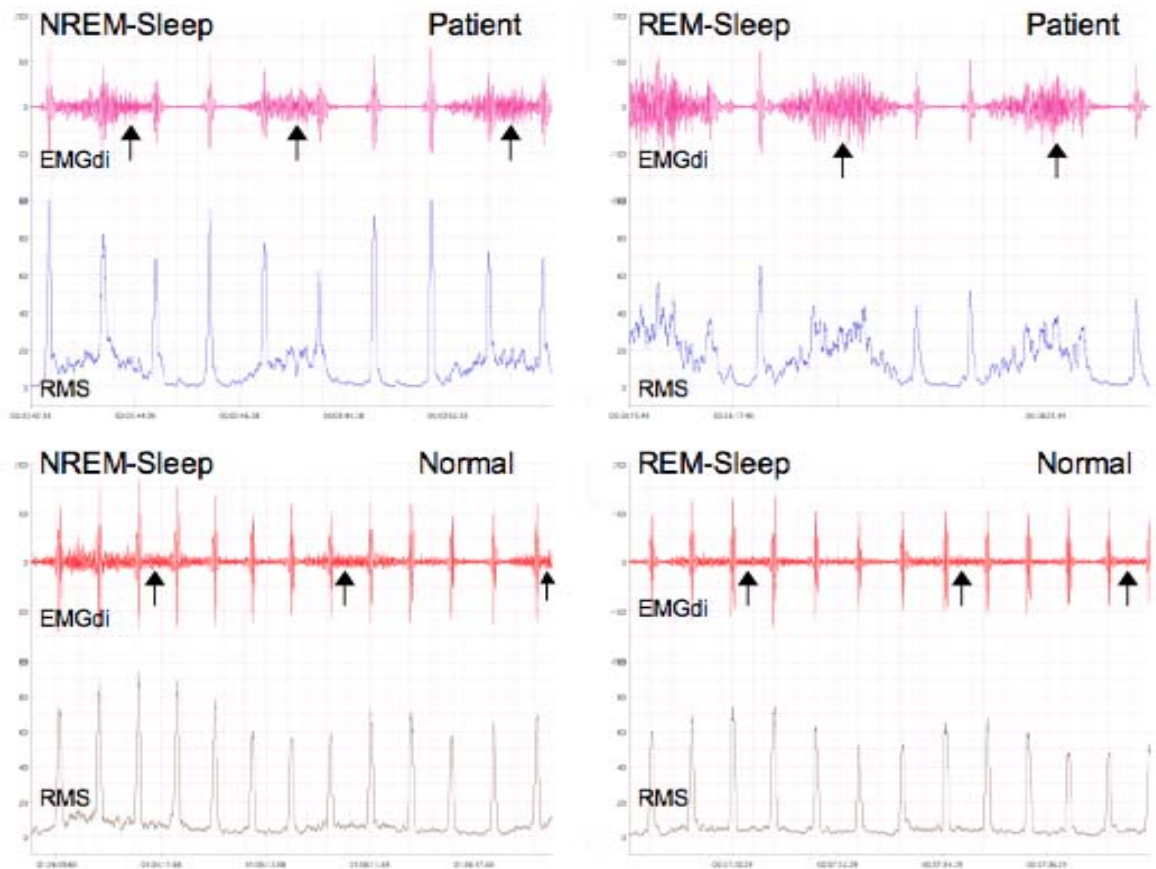

Figure 3

Figure 4: Neural respiratory drive, as measured with the diaphragm EMG (EMGdi), transdiaphragmatic pressure (Pdi), flow (pneumotachograph), genioglossus EMG (EMGgg) and oxygenation (SaO_2) during REM-sleep in a patient with UDP. The vertical dotted line indicates the first occurrence of phasic REM. Following a loss of initially high central drive, inspiratory effort reduces and the patient develops a hypopnoea that is eventually overcome by an arousal-reaction.
