Abstract:

We have investigated whether mast cells are associated with bronchodilator responsiveness and airway vascular changes in COPD airways. We have previously shown that the reticular basement membrane is hypervascular and the lamina propria is hypovascular in COPD.

Bronchial biopsies from 32 COPD subjects, 15 smokers with normal lung function and 17 controls were immunostained for Factor VIII, mast cell tryptase and chymase antibodies. Mast cells in the airway smooth muscle, the reticular basement membrane and the underlying lamina propria were quantitated. 41% of COPD subjects had significant bronchodilator responsiveness, but this was not related to smooth muscle mast cell numbers. The reticular basement membrane had greater mast cell density in all groups compared to controls (p<0.01). In this compartment perivascular mast cell density was related to hypervascularity. Lamina propria mast cell density was increased only in COPD (p<0.05). Perivascular mast cell density in the lamina propria was not related to its decreased vessel density.

Bronchodilator responsiveness in COPD is not related to large airway smooth muscle mast cells of either type; both reticular basement membrane and lamina propria mast cells are increased in COPD patients; perivascular mast cells may be involved in increased angiogenesis in the reticular basement membrane.
**Key Words:** Airway remodelling, airway vessels, bronchodilator responsiveness (BDR), chronic obstructive pulmonary disease (COPD), mast cells

**Abbreviation list:** ASM, airway smooth muscle; ATS, American Thoracic Society; BDR, bronchodilator responsiveness; BHR, bronchial hyperresponsiveness; COPD, chronic obstructive pulmonary disease; ERS, European Respiratory Society; ES-COPD, ex-smokers with COPD; FEV1, forced expiratory volume in 1 second; FVC, forced vital capacity; GOLD, Global Initiative for Obstructive Lung Disease; H-N, healthy and non-smoking controls; LP, lamina propria; Rbm, reticular basement membrane; MCT, tryptase positive mast cells; MCTC, tryptase-chymase positive mast cells; S-COPD, smokers with COPD; S-N, smoking normal subjects; VEGF, vascular endothelial growth factor
**Introduction:**

Mast cells are secretory cells that are replete with granules containing a wide variety of bioactive agents including proinflammatory, profibrotic, proangiogenic (e.g. vascular endothelial growth factor, VEGF) and antiangiogenic factors [1].

Mast cells are thought to contribute to bronchoconstriction, mucus secretion, mucosal oedema, bronchial hyperreactivity (BHR), inflammation, angiogenesis and airway remodelling in asthma [2-5]. In particular, an increase in the number of airway smooth muscle (ASM) layer mast cells has been suggested to be related to asthmatic BHR [3]. Bronchodilator responsiveness (BDR) has been shown to be related to BHR [6] and probably based on similar underlying mechanisms.

It is generally held that by definition airway obstruction in COPD is irreversible. However, significant BDR is in fact present in a large subgroup of patients with COPD, although they mainly get screened out from therapeutic studies [7, 8]. Some investigators have suggested that this BDR feature in COPD is related to “asthma-like” pathology, i.e. an overlap syndrome [9-11]. A substantial number of COPD subjects have been shown to have BHR [12, 13] with a significant correlation between BDR and BHR [14]. Therefore, given the relationships between both BHR and BDR in asthma and COPD, it is relevant to examine the smooth muscle layer in COPD airways for the number and type of mast cells, and its relationship to BDR in this setting.
Most cellular mediators can only effectively function close to the cells of origin to effect nearby target cells [3, 15]. We have previously reported hypervascularity in the reticular basement membrane (Rbm) and hypovascularity of the lamina propria (LP) in the airways of current smokers with COPD (S-COPD) and to some extent smokers with normal lung function (S-N) [16]. We questioned whether these vascular changes could be associated with alterations in the number of mast cells in these compartments, especially in close apposition to vessels. We hypothesised that: 1. patients with COPD who show BDR have higher mast cell numbers in the ASM layer; and 2. mast cells are increased in the Rbm and decreased in the LP, especially around blood vessels, in current smokers.

Methods:
We analysed endobronchial airway biopsies (BB) from 64 subjects including 17 S-COPD, 15 ex-smokers with COPD (ES-COPD), 15 S-N and 17 healthy non-smoking controls (H-N) to examine airway wall vascularity and mast cell density. GOLD guidelines were used for defining COPD [17]. All COPD subjects were on relief anticholinergics only. Subjects with other types of respiratory diseases, those with recent exacerbations or who had used systemic or inhalational steroids during the last 12 weeks were excluded. Study subjects had little if any chronic bronchitis.

The study was approved by the Human Research Ethics Committee (Tasmania) Network. All subjects provided written informed consent.
Pulmonary function tests were performed according to ERS/ATS guidelines [18]. BDR was defined according to ATS criteria, i.e. an increase of ≥12% and 200 ml from baseline FEV1 after 200 µg inhaled salbutamol [7].

Details of bronchoscopies and taking endobronchial biopsies have been described previously [16]. Eight biopsies from segmental bronchi in the right lower lobes were obtained from each individual. No complications were encountered.

Tissue processing: Of the biopsies, 4 were fixed in 4% neutral buffered formalin for 2 hours and subsequently processed into paraffin through graded alcohol and xylene using a Leica ASP 200 tissue processor. Three-micron sections were cut from individual paraffin blocks, stained with haematoxylin and eosin and morphologically assessed for suitability for immunostaining, being chosen to minimise tangential sectioning of the epithelium and to provide greatest length of epithelium. Two 3-micron sections, separated by a minimum of 50 microns from such blocks, were collected on each slide. Following removal of wax and hydration through descending grades of ethanol, sections were immunostained for mast cells using monoclonal mouse anti-human mast cell tryptase antibody (Anti AA1, DAKO M7052, 1 in 1500 for 20 minutes at 22 degrees C) or monoclonal mouse anti-human chymase (Abcam ab2377 clone CC1 at 1/100 dilution for 1 hour at 22 degrees C); (all antibodies were diluted using Dako diluent S0809). Serial sections were treated with mouse IgG1 isotype control (Dako X0931 at equivalent concentrations and conditions). A positive tissue control was included in all immunostaining. Endogenous peroxidase was quenched using 3% hydrogen peroxide in
water for 15 minutes prior to addition of primary antibodies and the sections being stained for mast cell tryptase were treated with 0.025% Type VIII protease (Sigma P-5380) in PBS for three minutes at 37º C to expose antigens. Subsequent to primary antibodies, DAKO EnVision+ (Dako K4001) was applied to the sections for 30 minutes. The sections were then incubated with diaminobenzidine (DAKO) as chromogen for 10 minutes. For sections stained for mast cell tryptase, immunostaining with monoclonal mouse anti-human von Willebrand factor (DAKO M0616, 1/50 for 2 hours at 22 degrees C) was undertaken for vessel staining. This antibody was elaborated using a “Real™” (DAKO 5005) biotinylated link followed by “Real™” (DAKO K5355) Streptavidin labeled alkaline phosphatase for 20 minutes each. Antibodies were visualized using permanent red (Dako K0640). Mayers haematoxylin was used to elaborate nuclei and eosin counterstaining was used to discriminate the smooth muscle fibers from surrounding tissue in the immunostained slides.

Measurements: Sections were randomized and coded independently of the histologist who examined them, blinded to diagnosis and order. Tissue examination was performed using a computer-assisted image analysis tool (Image-Pro version 5.1, Media Cybernetics, USA) at x400 magnification. As many non-overlapping pictures as possible were taken from each slide, and 8 of these separate fields were randomly chosen for enumeration. Only tissue samples with intact epithelium and basement membrane were selected for examination of the Rbm and LP (Figure 1). As prospective criteria, developed after pilot studies on our material, the amount of smooth muscle available for mast cell analysis had to be sufficient to constitute 30% of the length immediately below
the LP, and to have definite muscle bundles present. In general, this constituted approximately 0.03 mm² of smooth muscle per slide, which is less than described by Brightling et al. in their paper, although the specifics given were somewhat ambivalent [3].

The number and cross sectional area of vessels in the Rbm, and separately up to 150 µm from the antelumenal border of the Rbm in the LP (Figures 2 & 3), were quantitated and normalised to the length of the Rbm and the area of LP respectively [16]. As the results corroborated previous observations [16], i.e. hypervascularity in the Rbm and hypovascularity in the LP, these data are not reported. The numbers of tryptase-positive mast cells (MCT) in the Rbm (Figure 3) and the LP (Figures 2 & 3) were counted and normalised to the area of the Rbm and LP to calculate the density of mast cells per square mm of tissue. The number of MCT and chymase-positive mast cells (MCTC) in the ASM (Figure 4) were counted and divided by the surface area of compartment examined. Using an image analysis tool, a perimeter with a width of 10 µm was drawn around the margin of each vessel in the Rbm and LP; and the density of mast cells per square mm of tissue in this perimeter compartment was measured. Given the relative size of mast cells (usually 8-10 µm in diameter, but up to 20 µm) to the perivascular area of interest, any mast cell that was even partially located within this perimeter or in contact with the perimeter, was counted as being perivascular.

Analysis: Nonparametric ANOVA (Kruskal-Wallis) tested differences between all study groups; with post-hoc analyses for between two groups comparisons performed using
Mann-Whitney U tests when analysis revealed a significant difference according to a priori hypothesis. Spearman correlations were used to test relationships. All analyses were performed by PASW statistics 18 for windows. Two-tailed p values <0.05 were considered significant.

**Results:**

Sixty out of sixty-four subjects had enough tissue for both the Rbm and LP measurements. 39 out of 49 subjects who were included in the analysis for ASM measurements had adequate tissue per protocol (see Methods for details). Table 1 shows the demographics of the participants. 41% of S-COPD and 40% of ES-COPD had BDR according to ATS criteria (41% overall). 47% of S-COPD and 69% of ES-COPD suffered from mild COPD and the rest from moderate COPD (Chi-square p = 0.2) [GOLD, 2009 #283]. 42% of COPD with BDR and 67% of COPD with no BDR had mild disease and the rest moderate disease (Chi-square p = 0.2). Median post-bronchodilator change of FEV1 was 250 ml for all COPD subjects, 340 ml for COPD with BDR and 120 ml for COPD with no BDR.

65% of MCT in the ASM layer were stained positively for chymase. The density of ASM layer MCT was not significantly different between COPD with BDR, COPD with no BDR and H-N groups (nonparametric ANOVA, p = 0.8) (Figure 5), neither was there a difference in the density of MCTC between COPD with BDR vs. COPD with no BDR [median (range) 28 (0-69) vs. 47 (0-142) respectively, p = 0.3].
The average density of mast cells and perivascular mast cell density was significantly increased in the Rbm of the S-N, S-COPD and ES-COPD groups compared to H-N (non-parametric ANOVA test, p<0.001 and <0.01 respectively). S-N had also significantly increased perivascular mast cell density compared to ES-COPD (Figure 6).

The average density of mast cells in the LP was significantly increased in the S-COPD and ES-COPD groups compared to H-N (Figure 7). However, the density of perivascular mast cells was not significantly different between groups (Figure 7).

Correlations: No correlations were found between BDR (either as absolute change or % change in FEV1) and ASM mast cell density (either MCT or MCTC) in both COPD groups (r values between -0.01 and -0.3). However, only in the non-BDR COPD group, MCT density in the ASM was correlated with FEV1% predicted (r = 0.5, p<0.05) and MCTC density in the ASM was correlated quite strongly and positively with FVC (r = 0.8, p<0.01), FVC% predicted (r = 0.7, p<0.05), and negatively with FEV1/FVC ratio (r = -0.6, p<0.05).

Perivascular mast cell density in the Rbm correlated positively with number and area of vessels in S-COPD (r = 0.8, p<0.01, and r = 0.7, p<0.01 for number and area of vessels, respectively), in ES-COPD (r = 0.7, p<0.05 and r = 0.6, p<0.05) and the S-N groups (r = 0.8, p<0.01 and r = 0.9, p<0.001). Total mast cell density (but not perivascular density) in the LP correlated negatively with the area of vessels in this compartment only in the S-COPD group (r = -0.5, p<0.05). Age was on average greater in the COPD groups, although with substantial overlap with the other groups. Furthermore, there was no suggestion of a relationship between age (either within groups, or for the whole dataset) and any variables of interest in our study (as examples, in both COPD groups combined, for age versus Rbm mast cells, r = -0.02, p = 0.9; for age versus LP mast cells, r = -0.2, p = 0.4).

Discussion:
Our main airway pathophysiological findings can be summarized as:
1. There was no relation between mast cell density in the ASM in COPD subjects and variation in BDR for either tryptase or chymase cellular subtypes.

2. Increased perivascular mast cell density in the Rbm, found especially in current smokers, was positively related to Rbm hypervascularity.

3. Average mast cell density in the hypovascular LP was increased in both COPD groups compared to the control group, but not in normal smokers, but perivascular mast cell density was not different between groups, and not related to vessel number in the LP.

4. In COPD subjects without BDR there was a positive relationship between mast cell density and better airway function.

Some studies have reported “asthmatic features” in a subgroup of COPD patients and suggested an overlap asthma phenotype [9-11]. However, in contrast to the findings in asthma suggesting localisation of mast cells in the smooth muscle [15], our study did not find any differential localisation of mast cells in the ASM layer in COPD, nor specifically in those with more BDR, at least in the large airway biopsies under investigation. In general airway pathology is uniform throughout the airway system [19] and it is unlikely that BDR is solely a small airway function even in COPD. We feel that the findings do suggest that the pathophysiology of BDR is different between asthma and COPD, though it would be reassuring to have a repeat pathophysiological correlation study involving small airway tissue as well, though of course this would be logistically difficult.
There is a close relationship between BHR and BDR in asthma [6], and they are likely to be related entities. This relationship has also been shown in COPD where baseline airway caliber is less variable than asthma [14]. Similarly, Reid et al. did not find any particular asthma-type eosinophilic inflammatory feature which could differentiate COPD with BDR from COPD with no BDR [8]. Our findings are in keeping with other studies which found no changes in ASM mast cells in COPD [20-22] and no correlation between ASM mast cell number and BHR [22].

It has been shown that BDR is variable over time in COPD subjects [23]. Bronchodilator reversibility and BB were performed within 24 hours in our subjects, and we feel it is reasonable to use our data from these two procedures as representing a single epoch. It is unlikely that the cellular or physiological picture would be very different over 24 hours in stable subjects with no change in clinical or therapeutic status.

ASM mast cell densities, determined with both tryptase and chymase staining, were correlated positively with lung function parameters. Gosman et al. also found a similar positive correlation between ASM mast cell density in small airways and FEV1% predicted [24], but they also found a positive correlation between peripheral airway epithelial and subepithelial mast cell density and the FEV1/VC ratio. Overall these data suggest that mast cells are protective to the airways in COPD, or that they are fond particularly in earlier disease.
Our study revealed that perivascular mast cell density in the Rbm was positively associated with the number and area of vessels in that compartment, suggesting that mast cells may play a role in angiogenesis and hypervascularity in the bronchial Rbm in both smokers and COPD subjects. Our previous report of increased vessel-associated VEGF in the Rbm is compatible with this suggestion [16]. In the LP where vessel numbers were decreased, overall mast cell density was increased, but interestingly not so in the perivascular space, where they were relatively decreased compared to the rest of the LP. We did find a negative correlation between overall mast cell density and vascular area, and future studies should investigate whether these cells may be secreting anti-angiogenic factors [1].

Previous data on mast cells in COPD airways have given mixed messages, but none have deliberately differentiated between Rbm and LP compartments. Grashoff et al. studied small airways from current- and ex-smokers with COPD and reported more mast cells in the epithelium, but not in the remainder of the airway wall [25]. However, a group in Sweden found more mast cells in the epithelium, LP and ASM in biopsies taken from the main tracheal carina in asymptomatic smokers [26]. Others have not found an increase in airway mast cells in COPD, but used smokers with or without bronchitis as controls [27, 28]. Other studies which have found no difference in mast cell numbers between current smoker-COPD and normal non-smokers have had very small numbers of participants, with the possibility of type-2 statistical errors [29, 30].
Although our COPD subjects were generally older than the H-N and S-N groups, there was great overlap, and no suggestions of relationships between age and the outcomes of interest in this study, either in the whole dataset or in any subgroups. From 32 COPD subjects, only 25 had enough appropriate tissue (as per prospective protocols) for comparing ASM mast cell density between groups. This could raise a question about the power of the study, but Figure 5 makes it clear that a type-2 statistical error is quite unlikely.

**Conclusions:** Our study did not find the “asthma-type” picture of disproportionately more mast cell in the ASM layer in bronchial biopsies from the subgroup of COPD with BDR. Perivascular mast cell density was increased in the hypervascular Rbm in both the S-N and COPD groups, though it was predominantly a smoking-related effect. Mast cells were increased in number in the LP in COPD groups, but not in physiologically normal smokers, and were relatively fewer around the numerically depleted LP vessels. These are novel data, suggesting roles for mast cells in vascular airway remodelling in COPD, and potentially in preservation of airway function.
Funding sources: This study was supported by a NHMRC Australia project grant and the Royal Hobart Hospital Research Foundation through a Sypkes Fellowship. The funders did not have any role in the conduct of the research and the decision to publish it.
