Lung cavitation associated with Pneumocystis carinii infection in the acquired immunodeficiency syndrome: a report of six cases and review of the literature

ABSTRACT: Lung cavitation in patients with the acquired immunodeficiency syndrome (AIDS) and Pneumocystis carinii pneumonia (PCP) has mainly been reported as single case studies. Among 160 episodes of PCP seen in a 1,000 bed teaching hospital and a 600 bed teaching hospital from 1985–1992, we found six cases presented with lung cavitation and documented Pneumocystis carinii infection. In the cases we report, as well as in the cases reviewed, cavities appear either alone or within an area of pulmonary consolidation, a mass or a nodule. They may present with haemoptysis, show unusual locations and, most importantly, may frequently be misdiagnosed by bronchoalveolar lavage.

Among patients with acquired immune deficiency syndrome (AIDS), Pneumocystis carinii (PCP) is the most common pulmonary opportunistic infection, and is estimated to occur in approximately 60–80% of patients [1]. Its radiographic features, both in AIDS and non-AIDS patients, are typically described as a bilateral interstitial or alveolar pattern. Unusual and atypical roentgenographic manifestations include unilateral distribution, focal infiltrates, lobar involvement, atelectatic changes, cystic or honeycomb lesions, nodular densities, hilar enlargement, spontaneous pneumothorax, unilateral hyperlucent lung, pleural effusion, and lungs appearing roentgenographically clear in up to 5% of cases [2–12]. Lung cavitation is an unusual presentation of PCP, of which mainly single case reports have been published. In these cases, cavitation appears to develop in a nodule or mass, to be surrounded by, or to accompany, diffuse lung disease or consolidation, or manifest radiographically as single or multiple cavities, in which some cases are presumed to be abscesses [13–28].

Patients and methods

The records of six patients with PCP, radiographically presenting with cavitary lesions, were reviewed. These patients were seen at the Hospital de Bellvitge and the Hospital Mútua de Terrassa (a 1,000 bed and a 600 bed teaching hospital, respectively, in the Barcelona area) during the period from March 1985 to May 1992. During that time, 160 episodes of documented PCP were observed, 63% being the first AIDS-defining condition with a median of 24 cases per year (range 6–38). In our series, 66% of patients with PCP had intravenous drug abuse as a risk factor for AIDS, 22% were homosexual, 10% heterosexual and 2% were in other groups. Whenever induced sputum was negative, bronchoalveolar lavage (BAL) was performed, using a fibreoptic bronchoscope (Olympus BF type 20). The tip of the bronchoscope was wedged in a subsegmental bronchus, chosen on the basis of the roentgenographic findings. Bronchial wash specimens (20–30 ml) were obtained, after washing with 50–100 ml of saline solution. Staining methods included Gomori's methenamine silver and Giemsa.

In addition, all cases of cavitary forms of PCP reported in the literature were reviewed. Since a variety of cystic pulmonary lesions have been described in patients with AIDS and Pneumocystis carinii infection, we tried to include only those cases with cavities according to the definition given by the Nomenclature Committee of the Fleischner Society: "a lucency within a zone of pulmonary consolidation, a mass, or a nodule; hence, a lucent area within the lung that may or may not contain a fluid level and that is surrounded by a wall, usually of varied thickness" [29]. We have not included those cases cited only in PCP series but not clearly described.
Case reports

Case A

A 28 year old ex-drug addict was admitted to hospital because of fever, chest pain, and cough, with occasional haemoptysis. X-ray films of the chest showed a cavitary lesion with a fluid level in the right upper lobe (fig. 1). CD4 count was 65·mm⁻³. Stains and cultures from a BAL specimen were negative and amoxicillin/clavulanic was empirically instituted, with no improvement. A transthoracic needle aspiration (TNA) was performed, but cultures were negative. A pneumothorax subsequently developed, fever reappeared, and two days later a diffuse alveolar-interstitial pattern was seen in the left upper lobe. A second bronchoscopy was performed, and smears of the BAL stained with Gomori’s methenamine silver revealed 

\[ \text{Pneumocystis carinii} \]

Two months later, the lesions had almost disappeared (fig. 2), and the patient was later lost to follow-up.

Case B

A 34 year old ex-drug addict was admitted, presenting with a cavity in the left upper lobe. CD4 count was 100·mm⁻³. Smears and cultures from sputum and BAL were negative. Culture from a TNA sample revealed 

\[ \text{Haemophilus influenzae} \] and 

\[ \text{Streptococcus pneumoniae} \]

and a 6 week amoxycillin/clavulanic regimen was instituted. A chest X-ray remained unchanged, and a further bronchoscopy was carried out. Culture from a sample obtained through a protected catheter brush yielded 

\[ \text{Haemophilus influenzae} \] (40,000 colony forming units (cfu)). Thoracotomy was undertaken, with total excision of the lesion. Pathological findings revealed an interstitial lymphoplasmocytic infiltrate, and necrotizing granulomatous process, with intra-alveolar foamy exudates. The Gomori’s methenamine silver stain revealed the presence of encysted forms of \[ \text{Pneumocystis carinii} \].

Case C

A 31 year old man was admitted to the hospital because of fever and haemoptysis. A chest X-ray disclosed a 2×2 cm cavity in the left lower lobe. CD4 count was 6·mm⁻³. \[ \text{Pseudomonas aeruginosa} \] grew in several sputum sample. A fibreoptic bronchoscopy was performed, and bronchoalveolar lavage yielded \[ \text{Pneumocystis carinii} \] and no other micro-organisms. The patient was treated with co-trimoxazole at usual doses. One month after discharge, the cavity remained unchanged and the patient was once again admitted because of severe haemoptysis. A selective arteriography with embolization was necessary to control bleeding. \[ \text{Pseudomonas aeruginosa} \] grew once again from a protected catheter brush specimen. The patient died 6 months later after several bouts of fever, dyspnoea and cough, with persistent \[ \text{Pseudomonas aeruginosa} \] infection. At that time a 2×2 cm cavity was still visible.

Case D

A 29 year old homosexual and active drug addict was admitted to the hospital because of fever and haemoptysis. A chest X-ray disclosed a 2×2 cm cavity in the left lower lobe. CD4 count was 6·mm⁻³. \[ \text{Pseudomonas aeruginosa} \] grew in several sputum sample. A fibreoptic bronchoscopy was performed, and bronchoalveolar lavage yielded \[ \text{Pneumocystis carinii} \] and no other micro-organisms. The patient was treated with co-trimoxazole at usual doses. One month after discharge, the cavity remained unchanged and the patient was once again admitted because of severe haemoptysis. A selective arteriography with embolization was necessary to control bleeding. \[ \text{Pseudomonas aeruginosa} \] grew once again from a protected catheter brush specimen. The patient died 6 months later after several bouts of fever, dyspnoea and cough, with persistent \[ \text{Pseudomonas aeruginosa} \] infection. At that time a 2×2 cm cavity was still visible.

Case E

A 27 year old active drug addict was admitted to the hospital because of fever, cough with a mucopurulent sputum, and chest pain. He was being treated with zidovudine
and prophylactic aerosolized pentamidine (4 mg·kg\(^{-1}\) once a week). CD4 count was 190·mm\(^{-3}\). An X-ray showed consolidating lesions in both upper lobes and in the lingula, with multiloculated cavities (fig. 3). Streptococcus pneumoniae grew from blood cultures, but no radiological improvement was seen with cefuroxime. TNA and BAL were nondiagnostic. An open lung biopsy yielded Pneumocystis carinii. Co-trimoxazole was instituted with clinical and radiological improvement (fig. 4).

**Case F**

A 32 year old homosexual was admitted to the hospital because of intermittent fever and cough of two months duration. A chest X-ray showed a single cavity in the left upper lobe, surrounded by an interstitial infiltrate, and a similar infiltrate, in the right upper lobe with no gas-containing spaces. CD4 count was 74·mm\(^{-3}\). A fibreoptic bronchoscopy was performed and repeated, but specimens from BAL, and transbronchial biopsy (TBB) at the second procedure, were negative for stains and culture. A gallium-67 citrate scan showed intense focal uptake in both apical zones (fig. 5). An open lung biopsy was performed; a granulomatous reaction at the periphery, and central fibrosis with foci of necrosis containing Pneumocystis carinii organisms was observed. Some days later a pneumothorax developed which required drainage. Nine months later, a chest X-ray was normal.

**Discussion**

Since 1984, 29 cases of PCP with cavitary lesions (including our own) have been reported in the English, French and Spanish literature. All cases are summarized in table 1.

Only five of the cases had received prophylaxis with aerosolized pentamidine, but none with co-trimoxazole. In addition to the usual clinical findings of PCP, haemoptysis was found at presentation in some cases. From a radiological point of view, lesions tend to be intraparenchymal, and the unusual location in the upper lobes in 21 of the 29 cases reviewed is noteworthy.

Since the onset of the AIDS epidemic, many reports have dealt with the different cystic lesions (bullae, blebs, pneumatoceles or cavities) that may be found in PCP, although many of these lesions were also described before AIDS [30]. The major theories [4, 15, 23, 31–34] regarding the pathogenesis of these cystic lesions include: 1) alveolar-interstitial pneumonitis leading to cyst-like structures, probably due to elastinolytic proteases liberated by activated macrophages; 2) ischaemic necrosis due to invasion of the vascular lumina by Pneumocystis carinii; 3) concomitant or prior episodes of pulmonary infections; and 4) barotrauma as an additional factor in patients under mechanical ventilation.

However, clinical and morphological evidence of pulmonary destruction in AIDS may appear with no concurrent infection. Smoking, intravenous drug abuse and, in particular, prior and repeated infections (most often prior episodes of PCP) have been implicated in the appearance of premature bullous damage [35, 36]. Moreover,

in laboratory studies, human immunodeficiency virus (HIV) infection itself has been proven to have a direct cytotoxic effect on lung macrophages, that may liberate proteases and lyse insoluble elastin fibrils [37]. Taking into account all the above-mentioned arguments, it would seem that gas-containing spaces in the setting of AIDS and PCP may have a multifactorial origin.

All of our patients were smokers, but rather too young to show extensive emphysematous changes, and all but one were current or past intravenous drug users. We cannot be sure how this might have contributed to the clinical and radiological appearance, but in the biopsies performed there was no intravascular foreign material mixed with thrombi. Bacterial infection was found in three of the six patients. These concomitant infections may certainly have played a role in cavity formation. Nevertheless, the appearance of Pneumocystis carinii in the lung biopsies, and the response to anti-pneumocystis therapy leads us to suggest that this organism is a direct cause or contributor of cavitation.

The appearance of a granulomatous reaction in two of our patients (cases No. B and F) is noteworthy. PCP seems to be rarely associated with granulomatous inflammation. TRAVIS et al. [33] found six cases with granulomas, among 123 lung biopsies from 76 patients, and single cases have been reported [26, 38–40]. The granulomatous response probably tends to occur in nodular-appearing PCP and, although not proven, it is suggested that these patients might retain some degree of immunoresponsiveness.

In four patients (cases No. 8, 13, 24 (A) and 29 (F)), a pneumothorax was reported. In cases No. 24 (A) and 29 (F), the pneumothorax appeared shortly after invasive procedures were performed. In case No. 8, a moderate degree of pneumothorax developed adjacent to an area of cavitary nodular opacities in the right lower lobe, in the setting of PCP with a 3 month history. In case No. 13, a 39 year old man with three previous episodes of PCP, who subsequently received prophylaxis with aerosolized pentamidine, presented with cavitary lesions in the right middle and lower lobe, together with a pneumothorax requiring drainage. We believe that pneumothorax should be regarded as a potential complication in PCP with cavitary lesions. BERS et al. [41] have shown that in certain patients Pneumocystis carinii infection induces significant tissue destruction, with resultant bullae formation or cavitation, and subsequent spontaneous rupture leading to pneumothorax.

Surprisingly, among the 21 BAL procedures reported in the cases reviewed, including our own, only 11 yielded Pneumocystis carinii. This high incidence of false-negative results is a notable fact. Cavitaries arising in a nodule, lack of alveolar-interstitial infiltrates, or appearance in the upper lobes, may contribute to such results. This situation may have important implications in the management of these patients. Whether or not TBB may be more sensitive than BAL in cavitary forms of PCP is unknown. From 10 TBB in the 29 cases reviewed, four were negative (cases No. 3, 4, 11 and 29 (F)), and when both diagnostic components of bronchoscopy (BAL and TBB) were performed (cases No. 3, 4, 7, 10, 20 and 29 (F)) BAL was negative in five cases and TBB in three. Obviously, there are not enough cases to make definite conclusions, but in an HIV-infected patient with cavitary lesions, it seems reasonable to perform both BAL and TBB in an attempt to improve the overall diagnostic accuracy before an open lung biopsy is indicated.

In conclusion, PCP in AIDS may present with a great variability of cystic lesions, probably from a multifactorial origin. In the case of cavities, concomitant infections should, in particular, be considered. Patients frequently show lesions located in the upper lobes. Bronchoalveolar lavage, a highly specific and sensitive diagnostic procedure in “classic” PCP, often fails to reveal the presence of Pneumocystis carinii. It is probably worth performing both TBB and BAL in an attempt to improve the overall diagnostic accuracy.
