

Surfactant protein B polymorphisms, pulmonary function and COPD in 10,231 individuals

M. Bækvad-Hansen*, B.G. Nordestgaard*[‡] and M. Dahl*

ABSTRACT: The *surfactant protein (SP)-B* gene may influence chronic obstructive pulmonary disease (COPD) and, thus, personalised medicine. We tested whether functional polymorphisms in *SP-B* (rs1130866 (1580T>C), rs2077079 (-18A>C) and rs3024791 (-384G>A)) associate with reduced lung function and risk of COPD in the general population.

We genotyped 10,231 individuals from the general adult Danish population, and recorded spirometry and hospital admissions due to COPD. Because we previously found an association between the rare *SP-B* 121ins2 mutation and COPD among smokers, we stratified the analyses for smoking status.

None of the individual *SP-B* genotypes or genotype combinations were associated with reduced forced expiratory volume in 1 s (FEV₁) % predicted, forced vital capacity (FVC) % pred and FEV₁/FVC overall or among smokers ($p=0.25$ – 0.99). The odds ratio for spirometrically defined COPD did not differ from 1.0 for any of the *SP-B* genotypes or genotype combinations overall or among smokers ($p=0.17$ – 0.78). Similar results were obtained for hospitalisation due to COPD ($p=0.07$ – 0.93); we could exclude overall hazard ratios for heterozygotes of 1.18–1.21 and for homozygotes of 1.25–1.57 or larger for all three polymorphisms.

In conclusion, the functional rs1130866, rs2077079 and rs3024791 polymorphisms in the *SP-B* gene are not associated with reduced lung function or risk of COPD, making it unlikely that these variants will be useful in personalised medicine.

KEYWORDS: Asthma, chronic obstructive pulmonary disease, genetics, interstitial lung disease, lung cancer, pneumonia

Chronic obstructive pulmonary disease (COPD) is one of the leading causes of death worldwide and the number of deaths due to COPD is expected to rise in the future [1]. Smoking is the main risk factor for development of COPD; however, far from all smokers develop the disease. This suggests that other factors, such as genetic background, may play a role in susceptibility to COPD and, thus, be useful in personalised medicine. A variety of genes have been linked with risk of COPD, among these the surfactant protein (SP) genes [2–4].

SPs are essential components of the lung surfactant layer, which covers the terminal airways. The lung surfactant consists of phospholipids, cholesterol and proteins, and is primarily produced by alveolar type II cells [5, 6]. It forms a thin lipid layer on the surface of alveoli, which

reduces surface tension and prevents alveoli from collapse during expiration. Upon exocytosis from alveolar type II cells, surfactant initially exists as multilayered vesicular structures in the epithelial lining fluid. From these structures, it spreads to the surface as alveoli are extended and compressed during breathing.

SP-B is one of the four known SPs in humans. It is important for the formation of lamellar bodies and correct assembly of the surfactant layer [7]. Lack of SP-B cause fatal respiratory distress syndrome in newborns [8], and genetic markers in and around the *SP-B* gene have been associated with a spectrum of pulmonary diseases, including COPD [2–4, 9–13]. Three functional polymorphisms in *SP-B*, rs1130866, rs2077079 and rs3024791, have been associated with risk and/or severity of COPD. rs1130866 abolishes an N-linked glycosylation site in *SP-B*, while the two

COPD										
GOLD stage II	9	9	9	0.53	9	10	9	0.26	9	6
GOLD stage III–IV	4	5	4	0.21	4	4	4	0.86	4	7

Data are present as n (%), % or median (interquartile range), unless otherwise stated. The p-values were calculated by Kruskal–Wallis test for continuous variables and Pearson's Chi-squared test for categorical variables. Pack-yrs of tobacco smoked were based on ever-smokers. Passive smoking was defined as affirmative responses to the questions "Does anyone in your household smoke?" or "How many hours per day are you subjected to passive smoke?" Occupational exposure to dust or smoke was defined as an affirmative response to the question "Have you been exposed to occupational dust or fumes?" Asthma was defined as an affirmative response to the question "Do you have asthma?" COPD: chronic obstructive pulmonary disease; GOLD: Global Initiative for Chronic Obstructive Lung Disease.

TABLE 2 Patients with chronic obstructive pulmonary disease (COPD) according to sex and age

	All	Females		Males	
		Age <67 yrs	Age ≥67 yrs	Age <67 yrs	Age ≥67 yrs
Spirometrically defined COPD	1327 (100)	296 (22)	309 (23)	340 (26)	382 (29)
COPD hospitalisation	1186 (100)	347 (29)	297 (25)	278 (23)	264 (22)
Any COPD	1936 (100)	501 (26)	462 (24)	492 (25)	481 (25)

Data are presented as n (%). Spirometrically defined COPD: forced expiratory volume in 1 s (FEV₁)/forced vital capacity <0.7 and FEV₁ <80% predicted. COPD hospitalisation: International Classification of Diseases (ICD)-8 491–492 or ICD-10 J41–J44. Median ages used for stratification were determined among individuals who had spirometrically defined COPD or COPD hospitalisation (*i.e.* any COPD) for females and males separately.

promoter polymorphisms, rs2077079 and rs3024791, alter *SP-B* transcription levels [3, 14–18].

We hypothesised that the three common functional polymorphisms (rs1130866, rs2077079 and rs3024791) in the *SP-B* gene are associated with reduced lung function and increased risk of COPD in the general population. To test this hypothesis, we genotyped 10,231 individuals from the general adult Danish population, and recorded spirometry and hospital admissions due to COPD. We calculated odds and hazard ratios (HRs) to assess risk of COPD according to *SP-B* genotype, and we used power calculation to estimate the maximal risk of COPD we could potentially have overlooked.

MATERIALS AND METHODS

Subjects

We genotyped 10,231 individuals from the Copenhagen City Heart Study, a prospective general population study of individuals selected from the Central Population Register Code to reflect the adult Danish population aged 20 to ≥80 yrs [19]. The Copenhagen City Heart Study was initiated in 1976–1978 with follow-up examinations in 1981–1983, 1991–1994 and 2001–2003. DNA for genotyping was isolated from participants attending the 1991–1994 and/or 2001–2003 examinations. The study was approved by the local ethical committee: study numbers 100.2039/91 and 01–421/94, Copenhagen and Frederiksberg committee. All participants gave written informed consent. All participants were white subjects of Danish descent

Pulmonary function testing and COPD diagnoses

Forced expiratory volume in 1 s (FEV₁) and forced vital capacity (FVC) were determined with a dry-wedge spirometer (Vitalograph, Maids Moreton, UK). Each spirometry was performed in triplicate and results were accepted only if the variation between the two best measurements was <5%. The best results were used for calculation of FEV₁ % predicted and FVC % pred using multiple regressions on never-smokers for males and females separately, with age and height as covariates [19, 20]. Spirometrically defined COPD was taken as FEV₁/FVC <0.7 and FEV₁ <80% pred [4]. If individuals with asthma were excluded from this definition and/or individuals with Global Initiative for Chronic Obstructive Lung Disease (GOLD) stage I (FEV₁/FVC <0.7 and FEV₁ >80% pred) were included, the results were similar to those presented. Information on hospitalisation due to COPD (International Classification of Diseases (ICD)-8 491–492 and ICD-10 J41–J44) was collected in the

national Danish Patient Registry, which covers all hospitals in Denmark from 1976 to 2009.

Other pulmonary diseases

Asthma was defined as an affirmative response to the question “Do you have asthma?” Chronic bronchitis was defined as an affirmative response to the question “Do you bring up phlegm at least 3 months continuously every year?” Information on pneumonia, interstitial lung disease and lung cancer was collected in the national Danish Patient Registry and the Danish Cancer Registry. Pneumonia (ICD-8 480–486 and ICD-10 J12–J18), interstitial lung disease (ICD-10 J84) and lung cancer (ICD-7 162.0–2, 162.4–7, 163.0, 164.0, 199.2, 462.1–4, 464.4, 962.1–2, 962.4–6, 963.0 and 964.0, and ICD-10 C33–C34, C37–C38 and D02.1–2).

Genotyping

Genomic DNA was isolated from frozen whole blood (Qiagen, Hilden, Germany). The genotype analysis was performed in 2007 using the ABI PRISM® 7900HT Sequence Detection System (Applied Biosystems Inc., Foster City, CA, USA). Primers and probes for the TaqMan assays are listed in supplementary table 1. The TaqMan analysis was validated by sequencing of a subsample of the participants.

Statistical analysis

Statistical analyses were performed using STATA SE version 10.0 (StataCorp, College Station, TX, USA). A two-sided p-value of <0.05 was considered significant. From the three polymorphisms, we generated all possible genotype combinations. We used the Kruskal–Wallis test and Pearson’s Chi-squared test for differences in characteristics between *SP-B* genotypes (table 1). Main effects of *SP-B* genotypes in predicting FEV₁ % pred, FVC % pred and FEV₁/FVC were examined using the test for trends, while associations of *SP-B* genotype combinations with lung function were tested in ANOVA models. Odds ratios for COPD on spirometry by *SP-B* genotype or genotype combination were from logistic regression models including age, sex, smoking exposure in pack-yrs, passive smoking, occupational dust and fumes, education, and occupation. HRs for COPD hospitalisation during ≤33 yrs of follow-up by *SP-B* genotype or genotype combination were determined by Cox regression models with age as the timescale, adjusted for age, sex, pack-yrs, passive smoking, occupational dust and fumes, education, and occupation. We used NCSS-PASS (NCSS, Kaysville, UT, USA) to

calculate the low and high odds and HRs, which we had 90% power to exclude at two-sided p-values <0.05. Linkage disequilibrium between polymorphisms was estimated by Lewontins D' using STATA's pwld function.

RESULTS

Characteristics of the participants are shown in table 1. There were no differences in sex, age, smoking status or pack-yr of tobacco smoked for any of the *SP-B* genotypes. The distributions of *SP-B* genotypes for the three polymorphisms were in Hardy-Weinberg equilibrium (rs1130866: p=0.26; rs2077079: p=0.96; rs3024791: p=0.32). Pair-wise linkage disequilibrium for the three polymorphisms was determined by D'. rs2077079 and rs3024791 were in tight linkage disequilibrium (D'=0.97), whereas there was low linkage disequilibrium between rs1130866 and either rs2077079 or rs3024791 (D'=0.21 and 0.18, respectively). The relationship between spirometrically defined COPD and COPD hospitalisation, according to sex and age, is presented in table 2.

The proportion of males tended to be higher among those with spirometrically defined COPD and age >66 yrs, while the proportion of females tended to be higher among those with COPD hospitalisation and age <67 yrs. The proportions of females and males were similar among individuals with any COPD, *i.e.* spirometrically defined COPD or COPD hospitalisation.

Lung function

None of the individual *SP-B* genotypes or genotype combinations were associated with reduced FEV1 % pred, FVC % pred or FEV1/FVC (p=0.34–0.94; fig. 1). When stratifying for smoking status, the p-value for *SP-B* genotype combinations reached significance for FEV1 % pred and FVC % pred among never-smokers (fig. 2). On *post hoc* analysis, the *SP-B* TCAAGG and TCCCCG *versus* TCACGG genotypes were associated with increased FEV1 % pred (p=0.02 and p=0.01, respectively) and FVC % pred (p=0.02 and p=0.003, respectively) among never-smokers. Conversely the *SP-B* CCCCCG *versus* TCACGG

FIGURE 1. Lung function according to surfactant protein (*SP*)-*B* genotypes and genotype combinations. Data are presented as mean \pm SE. p-values for *SP-B* genotypes and genotype combinations were by test for trends and ANOVA, respectively. Numbers are slightly less than all individuals genotyped, as not all participants had spirometry performed. FEV1: forced expiratory volume in 1 s; % pred: % predicted; FVC: forced vital capacity.

FIGURE 2. Lung function according to surfactant protein (SP)-B genotypes and genotype combinations among never-smokers. Data are presented as mean \pm SE. p-values for SP-B genotypes and genotype combinations were by test for trends and ANOVA, respectively. Numbers are slightly less than all individuals genotyped, as not all participants had spirometry performed. FEV1: forced expiratory volume in 1 s; % pred: % predicted; FVC: forced vital capacity.

genotype was associated with reduced FEV1 % pred ($p=0.007$), FVC % pred ($p=0.04$) and FEV1/FVC ($p=0.01$) among never-smokers. These results are not biologically plausible and they could not be confirmed when testing spirometrically defined COPD or COPD hospitalisation. Among ever-smokers, none of the individual SP-B genotypes or genotype combinations were associated with reduced FEV1 % pred, FVC % pred and FEV1/FVC ($p=0.25$ – 0.99 ; online supplementary fig. 1).

Risk of COPD

The odds ratio for spirometrically defined COPD did not differ from 1.0 for any SP-B genotype or genotype combination, nor did the risk for COPD hospitalisation (fig. 3). We had 90% statistical power to exclude odds ratios for spirometrically defined COPD for heterozygotes of 1.22–1.24 and for rare homozygotes of 1.30–1.96 or larger for all three polymorphisms (fig. 3). Likewise, we had 90% statistical power to exclude HRs for COPD hospitalisation for heterozygotes of 1.18–1.21 and for rare homozygotes of 1.25–1.57 or larger for all three polymorphisms.

When stratifying for smoking status, the p-value for the rs1130866 polymorphism reached significance for COPD hospitalisation among never-smokers (fig. 4); however, none of the individual rs1130866 CC and TC genotypes differed significantly from 1.0, and the result could not be confirmed

when analysing spirometrically defined COPD. The risk for spirometrically defined COPD was increased in SP-B TTACGG and TCAAGA versus TCACGG among never-smokers (OR 2.5 (95% CI 1.2–5.5) and OR 2.7 (95% CI 1.1–6.7), respectively), and for COPD hospitalisation in SP-B CCAAAA versus TCACGG among never-smokers (HR 8.6 (95% CI 1.7–42.6)). None of these results could be confirmed when analysing the other COPD outcome of the study or when analysing the lung function. We, therefore, interpret these findings as likely spurious results.

Because the rs1130866 and the rs2077079 polymorphisms have been associated with severity of COPD and COPD exacerbations [3, 16], we examined the prevalence of COPD GOLD stages by SP-B genotype. The prevalence of GOLD stages II and III–IV did not differ by any of the SP-B genotypes ($p=0.16$ – 0.86).

Risk of other lung diseases

We also tested whether the three SP-B polymorphisms were associated with asthma, interstitial lung disease, pneumonia, chronic bronchitis or lung cancer (online supplementary table 2). None of the SP-B genotypes was associated with any of these lung diseases, except the rs3024791 AA genotype, which showed a 1.8-fold increased risk for asthma over GG.

FIGURE 3. Risk of chronic obstructive pulmonary disease (COPD) according to *surfactant protein (SP)-B* genotypes and genotype combinations. Spirometrically defined COPD: forced expiratory volume in 1 s (FEV₁)/forced vital capacity <0.7 and FEV₁ <80% predicted. COPD hospitalisation: International Classification of Diseases (ICD)-8 491–492 or ICD-10 J41–J44. Odds ratios for spirometrically defined COPD are by logistic regression. Hazard ratios (HR) for COPD hospitalisation are by Cox regression. Multivariate adjusted models allowed for age, sex, pack-yr, passive smoking, occupational dust and fumes, education, and occupation. p-values for *SP-B* genotypes and genotype combinations were by test for trends and ANOVA, respectively. The 90% power indicates the odds ratios that can be detected in this study at two-sided p<0.05. Numbers for the analysis of spirometrically defined COPD are slightly less than for COPD hospitalisation, because not all individuals had spirometry performed.

DISCUSSION

Genetic variation in *SP-B* has been linked to COPD in several association studies [3, 9, 16, 18] and, thus, could have importance for the development of COPD in the general population. We determined whether three functional polymorphisms in *SP-B* were associated with poor lung function and COPD in a large homogenous Danish population sample. We found, with significant power, that these polymorphisms were not associated with lung function or risk of COPD overall or among smokers. This makes it unlikely that the genetic variants can be used clinically to assess risk of COPD or to identify COPD subgroups for tailored therapy.

The C allele of the rs113086 polymorphism has previously, in studies with <1,000 participants, been associated with increased risk of COPD, severity of airway obstruction and disease exacerbation in COPD patients [3, 14, 16, 18]. In contrast, the present population-based study with >10,000 participants indicated that the rs113086 polymorphism does not affect risk of COPD, severity of COPD or risk of any other additional pulmonary disorder overall or among smokers. We did find a trend towards lower risk of COPD hospitalisation among never-smokers. However, this result could not be confirmed when analysing spirometrically defined COPD or lung function. We, therefore, interpret this as a likely spurious finding. Our data

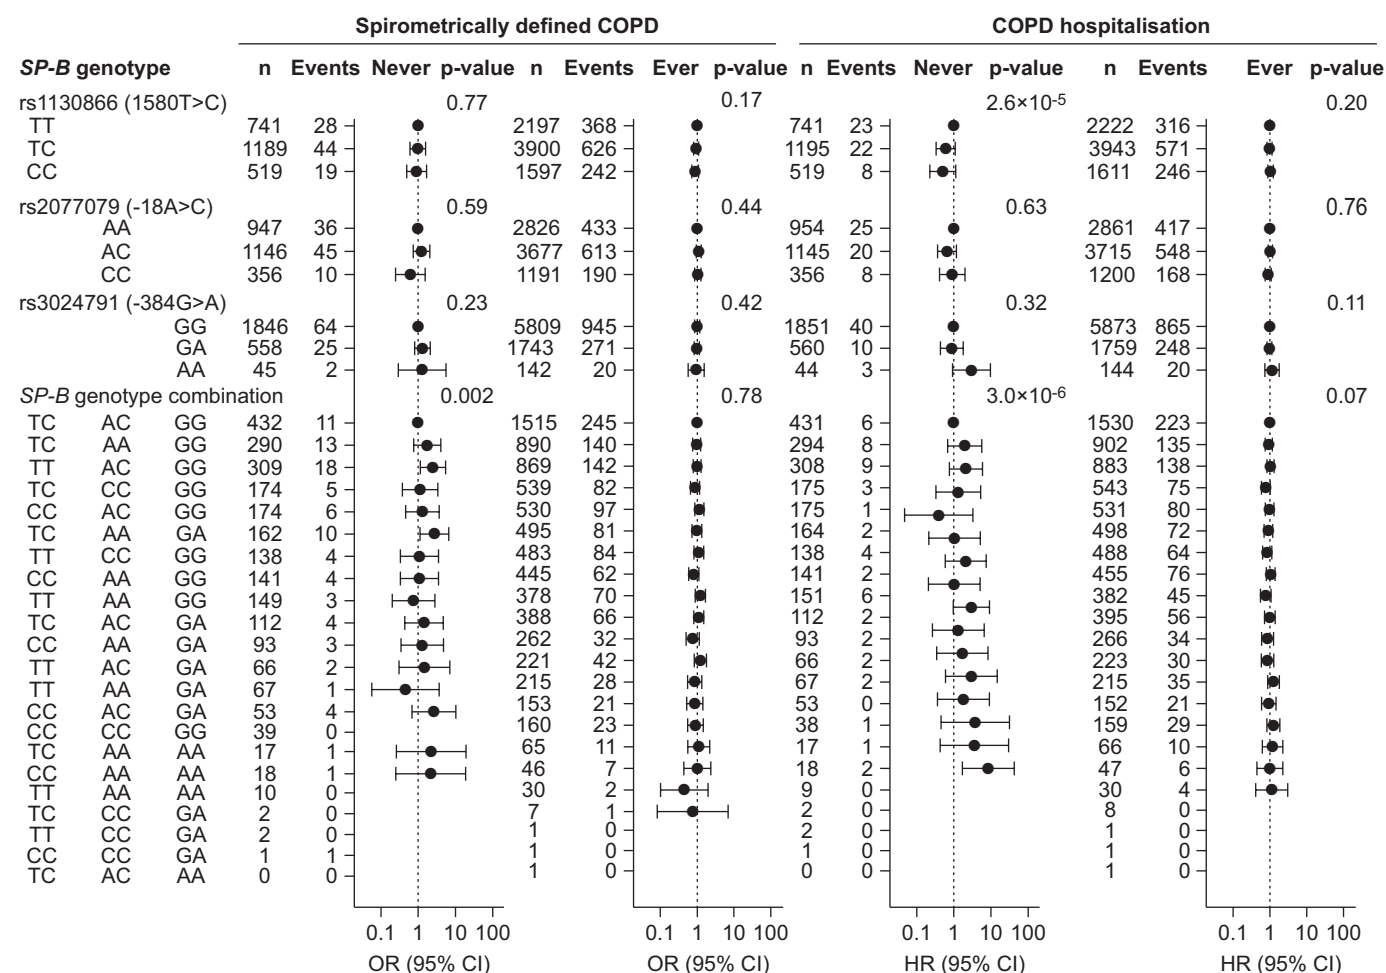

FIGURE 4. Risk of chronic obstructive pulmonary disease (COPD) according to surfactant protein (SP)-B genotypes and genotype combinations, stratified by smoking status. Ever-smokers: current and former smokers. Spirometrically defined COPD: forced expiratory volume in 1 s (FEV₁)/forced vital capacity <0.7 and FEV₁ <80% predicted. COPD hospitalisation: International Classification of Diseases (ICD)-8 491–492 or ICD-10 J41–J44. Odds ratios for spirometrically defined COPD are by logistic regression. The models allowed for age, sex, pack-yr, passive smoking, occupational dust and fumes, education, and occupation. p-values for SP-B genotypes and genotype combinations were by test for trends and ANOVA, respectively. Numbers for the analysis of spirometrically defined COPD are slightly less than for COPD hospitalisation, because not all individuals had spirometry performed.

on lung function are in accordance with a previous study on healthy males, which showed no association between rs1130866 and FEV₁ % pred or FVC % pred [21].

The SP-B promoter variations rs2077079 and rs3024791 have previously, in studies with <400 participants, been associated with severity of airway obstruction and exacerbations in COPD patients, but not with risk of developing COPD [3, 16]. Both polymorphisms alter transcription of the SP-B gene and may be associated with altered levels of SP-B in the airways. We did not find any overall association of the two promoter variants with lung function, risk of COPD or COPD hospitalisation. We have previously shown that partial SP-B deficiency due to the rare 121ins2 mutation is associated with reduced pulmonary function and increased risk of COPD among smokers [4]. However, when stratifying our data for smoking status, none of the two promoter polymorphisms were associated with reduced pulmonary function or risk of COPD among smokers.

It has been suggested that the rs1130866 polymorphism may require other interacting factors to alter the pulmonary

phenotype. GUO *et al.* [3] suggested that gene–gene and gene–environment interactions may be important, and HERSH *et al.* [18] found rs113086 to be associated with COPD only in a statistical model with the presence of a gene–smoking interaction term. To mimic gene–gene interactions and gene–environment interactions, we assessed lung function and calculated COPD risk estimates for combinations of rs1130866, rs2077079 and rs3024791 stratified by smoking status. When stratifying our analyses by smoking status, we were unable to show association of SP-B genotype combinations with lung function and risk of COPD among smokers. Among never-smokers, we did find an association between certain genotype combinations and lung function or COPD. However, these results may not be biologically plausible and they could not be confirmed using lung function or the other COPD end-point of the study. If correction for 60 and 30 multiple comparisons was performed for the analyses of SP-B combinations and lung function (fig. 2), and SP-B combinations and COPD (fig. 4), respectively, none of the results observed among never-smokers would be of statistical significance. We, therefore, interpret these findings

as likely spurious results. The lack of overall association of *SP-B* polymorphisms with pulmonary function and disease in our study is supported by recent genome-wide association studies and a novel Dutch population/case-control study [22–24].

As variations in *SP-B* have been associated with respiratory diseases other than COPD [9, 10, 25], we also tested for association between the three polymorphisms and risk of common pulmonary diseases, such as asthma, pneumonia and lung cancer. We found no consistent association between *SP-B* genotypes and any of the lung diseases we examined, except for asthma. As in previous reports on *SP-C* [26, 27], a protein related to *SP-B*, we did find an association between *SP-B* rs3024791 rare *versus* common homozygosity and asthma. We could not confirm this result when analysing other *SP-B* genotypes, and further studies will be needed to conclusively determine whether the *SP-B* rs3024791 AA genotype is associated with increased asthma risk.

Some misclassification of spirometrically defined COPD is possible, and this could limit the subgroup analysis according to GOLD classification. The pulmonary function tests used to define COPD were not performed post-bronchodilator due to the large number of subjects included in the study and our limited funds. However, excluding individuals with asthma from this definition did not substantially alter our results. Furthermore, in the 1991–1994 survey those individuals who had FEV₁/FVC <0.7 had post-bronchodilator spirometry performed. If analyses on pulmonary function and COPD were confined to this subgroup, we found no difference in FEV₁ % pred, FEV₁/FVC or COPD prevalences according to *SP-B* genotype or genotype combination. Lack of association between any of the *SP-B* polymorphisms with pulmonary function or disease, as opposed to previous findings, could be due to different genotype frequencies among the studied populations. HERSH *et al.* [18] reported a carrier frequency for the rs1130866 T allele of 0.44 for controls and 0.46 for cases. We found the overall frequency of the T allele to be 0.54. FOREMAN *et al.* [16] reported carrier frequencies for rs3024791 GG, AG and AA genotypes of 0.73, 0.25 and 0.02, respectively. Our results were very similar (0.75, 0.23 and 0.02, respectively). GOU *et al.* [3] reported a carrier frequency for the rs1130866 C allele of 0.67 for controls and 0.82 for cases. We found an overall carrier frequency for the rs1130866 C allele of 0.71. Bias caused by investigator knowledge of disease or risk factor status seems unlikely, because our sample was selected from the general population and genotyping of our sample was performed without investigator knowledge of disease status or lung function test results.

In conclusion, we find, with significant power, that three common functional polymorphisms in the *SP-B* gene are not associated with reduced lung function or risk of COPD in the Danish general population overall or among smokers. This makes it unlikely that these genetic variants will have a role in personalised medicine. Though our results are based on individuals of Danish/European descent, these polymorphisms are prevalent in many populations and our results may apply to other parts of the World.
